

Apparatus and Method for Reducing Motion of a Floating Vessel

The present invention relates to an apparatus and method for  
5 reducing motion of a floating vessel. In particular, but not  
exclusively, the invention relates to an apparatus and method  
for reducing the roll of a large floating vessel.

It is well known that ships, barges and other floating  
10 platforms roll, pitch and heave at sea and that such motion  
is undesirable in many fields. For example, such motion may  
be particularly undesirable when loading and unloading to and  
from the vessel. This is particularly the case for vessels  
involved with the offshore oil and gas industries. In that  
15 application it is common to unload and load, from and to a  
stationary structure e.g. a deck supported on a jacket on the  
sea bed or from and to another vessel.

Additionally, in the field of offshore gas and oil, the  
20 vessels may be extremely large so that, whilst the movement  
of the vessel is not very great when expressed in degrees of  
inclination, the movement at deck height is considerable,  
causing difficulties even in relatively calm conditions.

25 There are many known systems which aim to reduce roll and/or  
pitch motion of floating vessels. There are some systems that  
have been designed for relatively small vessels. For  
example, GB 2219973 describes a vessel in the hull of which  
there is a passageway which allows the free flow of water  
30 through it. As the passageway fills and drains, the natural  
period of the pitching/rolling motion is increased and the  
motion response of the vessel is reduced. In an improvement  
on this arrangement, such a tank may be connected to a pump  
so that the filling and draining of the tank can be  
35 controlled at least partially. However, such systems are

integral with the vessel itself and are difficult to install and costly and are not able to be easily transferred from one vessel to another.

5 Another system which aims to reduce instability of a larger vessel is described in US 5787832. In that system, stabilizer assemblies are attached to the hull of the vessel. Each assembly includes an outrigger arm and a float arm which has a float attached to one end. The floats are in contact with  
10 the water surface at all times and the system works by increasing the effective width of the vessel so as to increase the natural period of its rolling/pitching motion. Each stabilizer assembly has to be attached to the vessel through a very strong fastening that has to bear very high  
15 loads. US 3407766 describes another system which aims to reduce the instability of a larger vessel by providing a stabilizing body below the vessel and connecting it by rigid struts such as steel I-beams which are able to transmit a force moment back to the vessel. A major drawback to an  
20 arrangement of this kind is the very considerable strength required of the struts in order to transmit force moment from the stabilizing body to the vessel.

It is an object of the invention to provide an apparatus and  
25 method which avoids or mitigates the problems of known stabilizing systems described above.

According to a first aspect of the invention, there is provided a vessel comprising a first stabilizer assembly and  
30 a second stabilizer assembly, each stabilizer assembly comprising:

at least one submergible at least partially hollow body; and

suspending means for suspending the or each body from the vessel,  
the first and second stabilizer assemblies being suspended from substantially opposite sides of the vessel.

5

Such stabilizer assemblies can be installed in port or at sea and are able to be adapted to be used with any suitable vessel. Because they are at least partially hollow, they can be relatively large for a given mass and the suspending of  
10 the assemblies from the vessel can be accomplished relatively easily. Each stabilizer assembly is arranged to apply via the suspending means a downwardly directed force on the side of the vessel from which it is suspended when that side of the vessel moves upwards.

15

Typically, one stabilizer assembly is suspended from the port side of the vessel and one stabilizer assembly is suspended from the starboard side of the vessel. This reduces the roll of the vessel. The invention is, however, applicable to any  
20 kind of vessel some of which may not have clearly defined port and starboard sides (or bow and stern ends). It should be understood, however, that what are referred to herein as the sides of the vessel are those parts of the vessel that rise and fall when the vessel undergoes a rocking motion. The  
25 term does not necessarily refer to the port and starboard sides of the vessel.

Often the first stabilizer assembly will comprise a single submergible body but it may comprise:

30 a first submergible at least partially hollow body and a second submergible at least partially hollow body;

first suspending means for suspending the first body from the vessel; and

second suspending means for suspending the second body from the first body.

Similarly, the second stabilizer assembly will often comprise  
5 a single submergible body but it may comprise:

a first submergible at least partially hollow body  
and a second submergible at least partially hollow body;

first suspending means for suspending the first  
body from the vessel; and

10 second suspending means for suspending the second  
body from the first body.

The vessel may further comprise a third stabilizer assembly,  
the third stabilizer assembly comprising:

15 at least one submergible at least partially hollow  
body; and

suspending means for suspending the or each body  
from the vessel.

20 In one embodiment, the first stabilizer assembly is suspended  
near the bow of the vessel on one side, the third stabilizer  
assembly is suspended near the stern of the vessel on said  
one side and the second stabilizer assembly is suspended  
amidships on the other side of the vessel.

25

The above embodiments using three stabilizer assemblies are  
known as asymmetric arrangements.

Like the first and second stabilizer assemblies, the third  
30 stabilizer assembly may comprise:

a first submergible at least partially hollow body  
and a second submergible hollow body;

first suspending means for suspending the first  
body from the vessel; and

second suspending means for suspending the second body from the first body.

The vessel may further comprise a fourth stabilizer assembly,  
5 the fourth stabilizer assembly comprising:

at least one submergible at least partially hollow body; and

suspending means for suspending the or each body from the vessel.

10

The fourth stabilizer assembly may be suspended from the port or starboard side of the vessel.

In one embodiment, the first stabilizer assembly is suspended

15 near the bow of the vessel on one side, the second stabilizer assembly is suspended near the bow of the vessel on the other side, the third stabilizer assembly is suspended near the stern of the vessel on said one side and the fourth stabilizer assembly is suspended near the stern of the vessel  
20 on the other side.

In another embodiment, the first stabilizer assembly is suspended near the bow of the vessel on one side, the second stabilizer assembly is suspended near the stern of the vessel  
25 on said one side and the third and fourth stabilizer assemblies are suspended amidships on the other side of the vessel.

It will be understood that the assemblies may be arranged in  
30 any of a wide variety of configurations. If the submergible bodies of the assemblies are all of substantially the same size, then it may be advantageous for the same number of bodies to be provided on each side of the vessel.

The reduction of vessel motion relies upon the suspending means being able to apply downwardly directed loads resisting upward movement and the suspending means is therefore advantageously capable of bearing high tension loads. Whilst  
5 the suspending means may be capable of bearing high compressive loads too, that is not necessary and it may be more economical and simple not to provide for that. Thus the suspending means may be capable of bearing tension loads of more than one hundred times the loads it is capable of  
10 bearing in compression. The suspending means may comprise elongate flexible members, for example, chains, ropes or cables. The or each body is preferably attached to the suspending means at a plurality of locations; for example an elongate body may be attached to a respective elongate  
15 flexible member in the region of each of the opposite ends of the body.

Each body is preferably large and is also preferably elongate. Thus in a case where each body is elongate, it may  
20 have a cross-sectional area greater than  $4 \text{ m}^2$  and preferably greater than  $10 \text{ m}^2$ . Each body may comprise one or more closed or closable spaces having a combined volume of more than  $50 \text{ m}^3$  and preferably more than  $300 \text{ m}^3$ . The closed space or spaces are preferably sealed or sealable but they may  
25 alternatively allow some fluid transfer in and/or out of the space or spaces. In a case where the body is elongate it is preferably suspended with the longitudinal axis of the body substantially horizontal.

30 Each body may comprise at least one ballast tank. Preferably, each body comprises a plurality of ballast tanks, each separately ballastable. If the bodies are ballastable, the bodies can be suitably ballasted so that the rolling can be controlled to be dependent on the force and period of the

waves. Thus, the amount of damping of the rolling motion can be adjusted according to the conditions. In addition, if it is required to unload or load from or to the vessel to or from another vessel, the amount of damping can be adjusted to  
5 bring the vessel into line with the other vessel so that unloading and loading is facilitated.

Preferably, each stabilizer assembly further comprises at least one fin projecting from the or each body. The fins  
10 increase the drag on the bodies as they move through the water.

The size and shape of the fins is variable. For example, the fins may be straight or curved. In one embodiment, the at  
15 least one fin is pivotable relative to the or each body to restrict movement of the body in one direction (upwardly through water) more than in another direction (downwardly). This is useful because it is often required that there is  
more drag on the bodies when they are moving vertically  
20 upward than when they are moving vertically downward and the fins can be pivotable accordingly. Alternatively, the fins can be shaped so that there is more drag in one direction than in the other direction.

25 Preferably, each body is substantially cylindrical and/or prism shaped. In one embodiment, the body is in the form of a tube.

The body may have a round, and preferably a circular, cross  
30 section. Alternatively, the body may have a rectangular cross section, for example a square cross section. Alternatively, the body may have a triangular cross section.

In one embodiment, one or both ends of the body are substantially conical. This is advantageous because it facilitates transport. The bodies may, for example, be attached to the vessel to be towed beneath the water line to the desired location, at which point they can be attached to the vessel at the appropriate points. Having conical ends facilitates towing. The bodies may alternatively have hemispherical or rounded ends or any other shape which facilitates towing.

10

Consideration needs to be given to transferring loads from the suspending means to the vessel structure. Accordingly there is preferably provided a load transfer structure connected between the vessel structure and the suspending

15

means for transferring loads from the suspending means to the vessel structure. In a preferred embodiment of the invention the load transfer structure is provided by one or more saddles for attaching to the vessel, to support the suspending means. The saddles may be attached at the edge of the deck of the vessel at the port or starboard side. The saddles may be attached when the vessel is in port or when the vessel is at sea. The saddles extend the width of the vessel so that the bodies are suspended from points which are slightly further apart than the width of the vessel itself.

25

In the preferred embodiment of the invention it is only vertical loads from the suspending means that are to be transferred and it is therefore preferred that only vertical loads are arranged to be transferred from the suspending means to the vessel. That may result from the nature of the suspending means (for example if the suspending means is an elongate flexible member), or from the nature of a coupling.

30

The suspending means of the first stabilizer assembly may be connected to the suspending means of the second stabilizer assembly. That connection is preferably a structural connection made directly or indirectly. If made indirectly  
5 it is preferably made through an additional structure separate from the vessel structure.

According to a second aspect of the invention, there is provided an apparatus for reducing vessel motion comprising:  
10 a first stabilizer assembly and a second stabilizer assembly, each stabilizer assembly comprising:  
at least one submergible at least partially hollow body; and

suspending means for suspending the or each body from the vessel,  
15 the first and second stabilizer assemblies being suitable for locating at substantially opposite portions of the vessel. Each body may comprise at least one ballast tank. Preferably, each body comprises a plurality of ballast tanks, each  
20 separately ballastable.

Preferably, each stabilizer assembly further comprises at least one fin projecting from each body. Even more  
25 preferably, the at least one fin is pivotable relative to each body to restrict movement of the body in one direction more than in another direction.

Advantageously, each body is substantially cylindrical and/or  
30 prism shaped. In one embodiment, the body has a round, and preferably a circular, cross section. In another embodiment, the body has a rectangular cross section, for example a square cross section. In another embodiment, the body has a triangular cross section.

One or both ends of the body may be substantially conical, hemispherical or rounded. This facilitates transport by towing.

5

The apparatus may further comprise saddles for attaching to the vessel, to support the suspending means. The saddles may be attached at the edge of the deck of the vessel at the port or starboard side. The saddles may be attached when the

10 vessel is in port or when the vessel is at sea. The saddles extend the width of the vessel so that the bodies are suspended from points which are slightly further apart than the width of the vessel itself. This further stabilizes the vessel.

15

Preferably, the suspending means of the first stabilizer assembly is connected to the suspending means of the second stabilizer assembly. That connection is preferably a structural connection made directly or indirectly. If made indirectly it is preferably made through an additional structure separate from the vessel structure.

20

According to a third aspect of the invention, there is provided a submergible body in the form of an at least partially hollow tube, for reducing motion of a water-borne vessel comprising:

25

at least one ballast tank; and

at least one projecting fin for increasing the drag of the body through water.

30

Preferably the body comprises a plurality of ballast tanks, each separately ballastable.

In one embodiment, the tube has a circular cross section.

In another embodiment, the tube has a rectangular cross section, for example a square cross section. In another embodiment, the tube has a triangular cross section.

- 5 One or both ends of the tube may be substantially conical. This facilitates transport of the tubes by towing. Alternatively, one or both ends of the tube may be rounded or hemispherical or any other shape which facilitates transport by towing.

10

The or each fin may be pivotable relative to the tube to restrict movement of the body through water in one direction more than in another direction.

- 15 According to a fourth aspect of the invention, there is provided a method for reducing motion of a water-borne vessel comprising:  
suspending at least two, at least partially hollow  
bodies below the water line from substantially opposite  
20 portions of the vessel.

Preferably, the method further comprises ballasting each body.

- 25 It should be understood that in the description above, where a feature is described with regard to one aspect of the invention, it may also where appropriate be employed in respect of another aspect of the invention. Thus, for example, the method of the fourth aspect of the invention may  
30 be employed with a vessel of any of the forms defined according to the first aspect of the invention.

An embodiment of the invention will now be described with reference to the accompanying drawings of which:

Figure 1 is a plan view of a vessel including stabilizing apparatus according to the invention;

5 Figure 2 is a side elevation view of the vessel of Figure 1;

Figure 3 is a front elevation view of the vessel of Figures 1 and 2;

10

Figure 4 is a plan view of a vessel having a first alternative stabilizing arrangement;

Figure 5 is a side elevation view of the vessel of Figure 4;

15

Figure 6 is a plan view of a vessel having a second alternative stabilizing arrangement;

20 Figure 7 is a side elevation view of the vessel of Figure 6;

Figure 8 is a plan view of a stabilizing tube;

25 Figure 9 is a side elevation view of the tube of Figure 8;

Figure 10 is a cross sectional view of a stabilizing tube having an alternative construction;

30

Figure 11 is a cross sectional view of a stabilizing tube; having a second alternative construction;

Figure 12 is a cross sectional view of a stabilizing tube

having a third alternative construction; and

Figure 13 is a plot showing the effect of the stabilizing arrangement on the degree and period of rolling motion.

Figures 1, 2 and 3 show a vessel 2 having a stern 4, a bow 6, a port side 8, a starboard side 10 and a deck 12. Suspended from the vessel are four tubes 14, two tubes close to the port side 8 and two tubes close to the starboard side 10. One port side tube 14a is located near the bow of the vessel. One port side tube 14b is located near the stern of the vessel. One starboard side tube 14c is located near the bow of the vessel. One starboard side tube 14d is located near the stern of the vessel. Each tube 14 is suspended from the vessel by two chains 16. The chains 16 from opposite tubes 14a, 14c and 14b, 14d are linked close to the centre of the deck 12. As shown in the drawings the tubes are arranged with their longitudinal axes horizontal.

Saddles 18 located at the edge between the deck 12 and the port side 8 and the deck 12 and the starboard side 10, support the chains 16. This ensures that the chains 16 remain clear of the sides of the vessel even when the vessel rolls a certain amount.

Each tube 14 is substantially cylindrical. Each tube includes a number of ballast tanks (not shown) which can be separately ballasted and deballasted thus allowing the mass of the tubes 14 in the water to be controlled. Each tube 14 also includes two horizontal fins 22. The horizontal fins 22 impede movement at speed of the tubes 14 in the vertical direction.

As the vessel rolls, the port side 8 and the starboard side 10 alternately rise and fall. As the port side 8 rises, the port side tubes 14a and 14b are required to move upwards and the mass of the tubes and the projecting fins impede that upwards motion. More particularly, the necessary acceleration upwards of the tubes is limited by the inertia of the tubes, whilst the tubes and fins are also resistant to travel through the water at high velocity. Similarly, as the starboard side 10 rises, the starboard side tubes 14c and 14d are required to move upwards and the mass of the tubes and the projecting fins impede that upwards motion. Thus the rolling motion of the vessel 2 is reduced; the degree of rolling is reduced and the period of the motion is increased i.e. the frequency is reduced.

15 The tubes, chains and saddles may be attached to the vessel in port or at sea.

The diameter and length of each tube is variable to suit the application. The material used to construct the tube is variable and this will depend upon the desired mass of each tube. The mass of each tube affects the acceleration of the tubes through the water. The number of ballast tanks in each tube is variable and the tubes are designed to be ballastable on deck so that the tubes can easily be towed in the water to facilitate transport. The cross section of the tubes is also variable (see Figures 10 to 12). The tubes may have conical ends in order to facilitate transport. The length of the chains is also variable. The size and shape of the fins is variable and the fins may be pivotable in relation to the tube such that, as the tube moves vertically upwards the fins project horizontally to impede the upwards motion, but as the tube moves vertically downwards the fins pivot inwards so as

not to impede the downwards motion. The size and shape of the fins affect the speed of the tubes through the water.

In one embodiment, the tubes are 40m long, with conical ends, and 5m in diameter. Each tube weighs 200 tonnes and comprises ten separate ballast tanks. Each tube has two projecting 75 cm fins, which extend along all of the tube and cones. The tubes can be suspended 25m below the water line.

10 Figures 4 and 5 show an alternative arrangement for the tubes on the vessel. This is known as the asymmetric arrangement. In this case two tubes 14 are suspended close to the port side 8 and one tube is suspended close to the starboard side 10. One port side tube 14a is located near the bow of the vessel and one port side tube 14b is located near the stern of the vessel. The starboard side tube 14c is located amidships. Of course, there could alternatively be two tubes on the starboard side and only one tube on the port side.

20 Figures 6 and 7 show another alternative arrangement for the tubes on the vessel. This is known as the ladder arrangement. In this case two tubes 14 are suspended close to the port side 8 and two tubes are suspended close to the starboard side 10. One port side tube 14a is located near the bow of the vessel and one port side tube 14b is located near the stern of the vessel. Both starboard side tubes are located amidships, the second starboard side tube 14d being suspended beneath the first starboard side tube 14c. Of course, there could alternatively be two tubes amidships on the port side, one stern starboard side tube and one bow starboard side tube.

Alternative arrangements are also envisaged, which are not explicitly illustrated, for example a double ladder

arrangement having two tubes amidships on the port side and two tubes amidships on the starboard side.

Figures 8 and 9 show the tubes 14 in more detail. Each tube 5 14 has two horizontal fins 22 projecting from the tube 14. Each tube 14 also has lifting points 24 shown schematically in Figures 8 and 9. On the tube 14 shown in Figure 9 there are four lifting points 24, two on the upper side of the tube and two on the lower side. The two lifting points 24 on the 10 upper side allow the chains 16 to be attached for suspending the tubes from the vessel. The two lifting points 24 on the lower side are only useful when the tube is used in the ladder arrangement shown in Figures 6 and 7. However, in many cases, it is advantageous for all the tubes to have four 15 lifting points 24 so that the construction of every tube is the same and any tube can be used in any application.

Figures 10 and 11 show a tube 14 having a square cross 20 section. Such a cross section gives the tube a greater drag through the water. In Figure 10 the horizontal fins project from the side of the square tubes. In Figure 11, the horizontal fins project from the base of the square tubes.

Figure 12 shows a tube 14 having a triangular cross section. 25 Such a cross section gives the tube increased drag when moving vertically upward but reduced drag when moving vertically downward. As the vessel rolls, the port side and the starboard side alternately rise and fall. As the port side falls, the tubes on the port side are required to move 30 downwards through the water. It is therefore advantageous if there is as little drag in the downwards direction as possible. Conversely, as the port side rises, the tubes on the port side are required to resist movement upwards through

the water. It is therefore advantageous if there is as much drag in the upwards direction as possible.

Other cross sectional shapes may also be envisaged and these  
5 shapes will have different effects on the speed and acceleration of the tubes in the water, as the vessel rolls.

It is particularly advantageous if the size and shape of the tubes takes into account the use of the tubes in other  
10 applications. Additionally, the storage of the tubes should be considered. For example, in the field of offshore oil and gas, the tubes may be storable horizontally on the deck of a stationary structure, on a vessel or on shore. Alternatively, the tubes may be stored in the sea when they are not in use.  
15 They may, for example, be stored horizontally on the sea bed, preferably with a warning buoy floating on the sea above them, or a group of tubes may be rotated into upright positions, tied together and moored at sea in a floating arrangement with parts of the tubes projecting upwards above  
20 the surface and parts submerged below the surface.

When considering the effect of the stabilizing apparatus on the rolling motion of the vessel, there are two factors to be considered: the frequency of the rolling motion and the  
25 amplitude of the rolling motion. The natural frequency of the rolling is dependent on the mass of the system, since, as the mass of the tubes increases, the natural period of the rolling motion of the vessel increases. The amplitude of the rolling is dependent on the damping forces applied to the  
30 system and as the damping force increases, the amplitude will decrease i.e. the amplitude is dependent on the geometry of the tubes. Thus, as the diameter of the tubes and the size of the fins increases, the amplitude of the rolling motion of the vessel decreases.

Referring to Figure 13, the effect of the stabilizing apparatus can be seen very clearly. Figure 13 shows the amplitude of rolling as a function of the period of the applied wave motion. The x-axis shows the period in seconds and the y-axis the roll RAO in deg/m. The top plot is the base case i.e. the vessel without any stabilizing apparatus. It can be seen that the natural period of the vessel is close to 10 s. The middle plot is a middle case where the vessel is fitted with stabilizing apparatus in which the tubes have a diameter of 3 m and the fins project 500 mm. It can be seen that the natural period of the vessel is close to 11 s. The bottom plot is a further case where the vessel is fitted with stabilizing apparatus in which the tubes have a diameter of 5 m and the fins project 500 mm. It can be seen that the natural period of the vessel is close to 12 s.

Thus, it can be seen clearly from Figure 13 that the effect of the stabilizing apparatus is to reduce the amplitude of the rolling motion of the vessel (i.e. the peak of the curves decreases) and to increase the period of the rolling motion of the vessel (i.e. the peak of the curves moves to the right in the x-direction).

The description above is somewhat simplified and, as previously mentioned, there are many other variables which will affect the amplitude and period of the rolling motion e.g. the cross-sectional shape of the tubes and the size and shape of the fins.

Whilst certain specific embodiments of the invention have been described, it should be understood that many variations are possible. In particular, if the tubes 14 are not in use stabilizing a vessel, they may be put to a variety of other

uses. For example a tube may be floated with its longitudinal axis horizontal and used as a mooring buoy. Alternatively it may be used as a flotation tank for transporting a structure and may further be used, after  
5 appropriate ballasting, for raising a structure from the seabed or lowering a structure to the seabed.
